PREFACE.

This study of the conductivity and dissociation of electrolytes, and of the temperature coefficients of conductivity, was begun eleven years ago in connection with the solvate theory of solution, which had been proposed in this laboratory shortly before that time. Certain relations of interest, and I hope of some importance, between the temperature coefficients of conductivity and the magnitude of the hydration of the dissolved salt were pointed out.

The work, thus begun, was continued especially for the following reason: When reference was made to the literature for the conductivity of any electrolyte at any given temperature, and for the temperature coefficients of conductivity, we were frequently unable to find what was desired; or, if found, the data were often so discordant that it was impossible to decide what were the true conductivities and dissociations in question.

Since the magnitude of the dissociation of any electrolyte is fundamental to its scientific use in chemistry, it seemed desirable that such data should be made available over the range of temperature most frequently used in the laboratory. With this idea in mind the work has now been continued here until it represents more than twenty years' continuous labor for one man, about 40,000 conductivity measurements having been made. Every one of the investigators has worked from one to two years on the problem, and Doctors Springer, West, and Wightman have each continued their investigations between two and three years.

The result is, that the conductivities and dissociations of about 110 of the more common salts have been worked out from zero to sixty-five degrees, and over a range in dilution extending from about the most concentrated solution that could be used to the dilution of complete dissociation. The temperature coefficients of conductivity have been calculated in both conductivity units and percentages. Moreover, similar data have been obtained for about 90 of the more common organic acids, and their constants have been calculated by means of the Ostwald dilution law.

It is hoped that this work, which has consumed much of the best energy of my laboratory for several years past, may prove to be of some value to other investigators in the field of general or physical chemistry.

HARRY C. JONES.

INTRODUCTION.

THE METHOD.

The method of measuring the conductivity of the solutions, employed throughout this work, was essentially that of Kohlrausch. The bridge used in most of the work was the latest improved form made by Leeds and Northrup, consisting of a manganine wire between 4 and 5 meters long, wound around a marble cylinder. The wire was calibrated by the method of Strouhal and Barus.*

The resistance coils were standardized against a rheostat which had been corrected by the United States Bureau of Standards. A number of forms of telephone receivers were tried, and finally a sensitive form furnished by Leeds and Northrup was adopted. The very satisfactory inductoria were also made by Leeds and Northrup.

Three separate readings on the bridge were made for each solution at each temperature, different resistances being, of course, used for each reading. The average of the conductivities obtained by these measurements, which differed only slightly from one another, was taken as the true conductivity of the solution. The measuring flasks and burettes used in this work were generally calibrated by the method of Morse and Blalock.† For the work from 0° to 35° the measuring apparatus was all calibrated at 20°, and the results at lower and higher temperatures multiplied by the proper factor. For the work from 35° to 65° the measuring apparatus was usually calibrated at 50°, and the proper correction inserted into the results at the lower and higher temperatures.

The conductivities are all expressed in terms of potassium chloride solutions which were used for standardizing the cells.

CONDUCTIVITY CELLS.

The form of cell used in this work is shown in fig. 1. The glass tubes carrying the electrodes are sealed firmly into the tops and bottoms of the ground-glass stoppers, and these tubes are sealed down tightly on to the platinum plates serving as electrodes. The plates are thus held firmly in position, and the distance apart is fixed for any given cell.

In making a series of readings at any given temperature, as many cells were used as there were solutions of different concentrations of the salt in question to be measured. Eight such cells constituted a set, and the distances between the plates and the sizes of the plates were adapted to the concentrations to be studied.

The conductivity of the water was determined in a cell especially constructed for this purpose. It consisted of two concentric platinum cylinders, about 1 mm. apart and 6 cm. long, shown in fig. 2. Glass tubes carrying platinum wires were sealed down on to the tops of these cylinders. These glass tubes were firmly sealed into the top and bottom of the ground-glass stopper.

---

*Wied. Ann., **10**, 326 (1880). †Amer. Chem. Journ., **16**, 479 (1894).

The cells were generally covered with a little platinum black, to increase the sharpness of the minimum in the reading on the bridge. The cylindrical type of cell, however, was never blackened.

The platinum plates used as electrodes were cut from sheet platinum about 1 mm. thick. The relatively thick plates were much less liable to bend and change the constant after it was once determined.

CELL CONSTANTS.

The cell constants were determined with standard solutions of potassium chloride whose molecular conductivity at 25° was determined with a high degree of accuracy. The cells to be used with the more concentrated solutions, and whose plates were therefore most widely apart, were all standardized with a $n/50$ solution of potassium

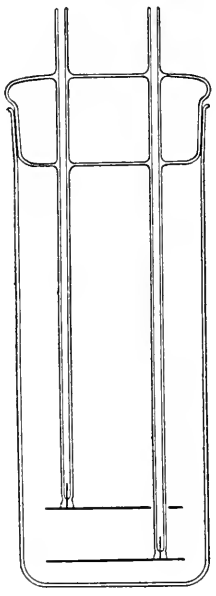

FIG. 1.

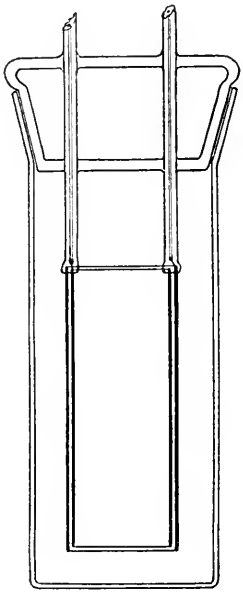

FIG. 2.

chloride. The cells to be used with the more dilute solutions were all standardized with a $n/500$ solution of the same salt, while the cylindrical cells were standardized with a $n/2000$ solution of potassium chloride. The solutions of potassium chloride of different concentrations were used for the different cells, in order that the resistance to be thrown into the rheostat would be of the order of magnitude to give a sharp reading on the bridge.

The cell constants in every set of cells used in this work were redetermined once or twice a month during the entire time that this series of investigations was in progress. With reasonably careful handling the constant of any cell underwent very small change during an entire year's work.

When the cells were used over the temperature range 35° to 65°, certain precautions were necessary in connection with the constants. It was found that at these

higher temperatures a strain seemed to develop in the cells unless they were kept at a fairly uniform temperature. This resulted in a small change in the cell constants, due either to a change in the distance between the plates or in the surfaces of the plates themselves. Errors would be introduced, especially in the case of those cells whose plates were close together—which had small cell constants.

Since such a variation as that referred to above had not previously been observed over the temperature range 0° to 35°, it was thought that the changes in the cell might be reduced to a minimum by keeping the cells at a temperature which was about the mean of those employed in the experimental work. Accordingly, the cells, when not in use, were filled with pure water and placed in a bath which was maintained continuously at a temperature of from 45° to 50°.

To test the accuracy of the procedure adopted the following experiments were carried out. The conductivities of several different substances at the three dilutions, 5, 1024, and 2048 liters were measured in the cells ordinarily used for solutions of these concentrations. The measurements were first carefully made at 35°, then the solutions warmed to 65° and their conductivities determined. The solutions were then cooled down to 35° and their conductivities redetermined. If the conductivities found the second time at 35° agreed with those initially found at this temperature, it would be some evidence as to the reliability of the method used. In about half the cases the two sets of measurements at 35° agreed very satisfactorily, In the other half, the second readings differed slightly from the first, and the difference seemed to be independent of the cell employed or the concentration of the solution used.

In all of those cases where any difference was detected between the initial and final conductivities at 35°, this difference always disappeared entirely on allowing the cells to stand at 35° for two or three hours. This showed that any slight change that the cell might have undergone at the higher temperature disappeared when the cell was kept for a time at the lower temperature.

SOLUBILITY OF GLASS.

In conductivity work at ordinary temperatures this factor has always been neglected and probably is not sufficiently large to influence the results, even with very dilute solutions. However, at 50° the error introduced by this factor at a dilution of 1000 is greater than any of the other ordinary experimental errors. At 65° the solubility of the glass is still greater, and at 80° the conductivity of pure water is increased tenfold on remaining in the cell for a couple of hours. In this connection it may be stated that the cells employed were made of hard glass. Of course, the amount of glass dissolved depends upon the exact nature of the latter, and was found to vary considerably with the different cells used, and at different intervals in the case of any one cell. The idea of introducing a correction for the solubility of the glass was abandoned, but the difficulty was overcome in another way. It was found that after the cells had been heated with water, acid, and alkali for several days, the amount of glass dissolved gradually decreased and finally amounted to practically nothing. After this treatment, as the cells were kept in a bath at 45° to 50° and the water in them changed once a day, the solubility of the glass at 65°

was always negligible. It is quite certain that for cups made and treated as above described the solubility of the glass does not stand in the way of accurate work up to 65°.

Since the solubility of glass increases very rapidly with the temperature above 65°, it was decided not to carry these measurements of conductivity to a temperature higher than 65°.

PREPARATION OF THE SOLUTIONS.

All of the substances used were obtained from Kahlbaum. These were purified by the method best adapted to each substance, and the purity of the compound tested in every case.

Whenever the nature of the compound permitted, the mother solution was prepared by directly weighing out the amount of the pure compound desired. In other cases the mother solution was standardized by the best gravimetric method available for that purpose. In the case of the organic acids the mother solution was frequently standardized by titration against a standard solution of an alkali.

Two sets of solutions of every compound were prepared—the one to be used for measurements from 0° to 35°, and the other set to be studied from 35° to 65°. The solutions to be used over the temperature range 0° to 35° were made up at 20°, and those solutions to be measured from 35° to 65° were generally made up at 50°, in vessels calibrated for 20° and 50° respectively. Since the coefficient of expansion of water increases greatly with the temperature, it is necessary to apply the proper correction to the conductivities of solutions taken at 35° and 65°, when the solutions were made up at 50°.

When a standard solution is cooled from 50° to 35° there is a contraction in volume and a consequent increase in the concentration of the solution. The value of μ_v for any solution would, therefore, be slightly too large. The value of μ_v as found must be multiplied by the factor 0.994 for results at 35° when the solutions were made up at 50°. The correction factor for solutions made up at 50° and used at 65° is 1.0076.

The coefficient of expansion for distilled water is somewhat less than that for an aqueous solution. However, the difference in the coefficients for water and for our most concentrated solution is so small that it is negligible.

By making use of the above correction it was necessary to prepare only one set of solutions for each salt for the temperature range, 35° to 65°; and, consequently, much pure material and time were saved.

By preparing one set of solutions to be used from 0° to 35°, and another set of solutions from entirely new material for use from 35° to 65°, we had a test of the purity of the material used, the proper standardization of the solutions, and the correctness of the conductivity values herein given. The two sets of solutions were both measured at 35°, and when discrepancies in the two sets of results, of appreciable order of magnitude, manifested themselves; as was inevitable in some cases where about 40,000 measurements were made, the work was repeated over the higher range in temperature, or over the lower range in temperature, or over the entire temperature range.

From these two mother solutions all of the more dilute solutions were prepared, directly or indirectly, using carefully calibrated flasks and burettes.

WATER.

All of the water used in this work was purified by the method worked out a number of years ago in this laboratory by Jones and Mackay.* It consisted in distilling the distilled water of the laboratory from chromic acid (potassium dichromate and sulphuric acid), which burned up any organic matter present in the water, and then redistilling the water from barium hydroxide. The sulphuric acid held back all ammonia formed from the organic substances, while the barium hydroxide combined all the carbon dioxide formed from the oxidation of the organic matter by the chromic acid.

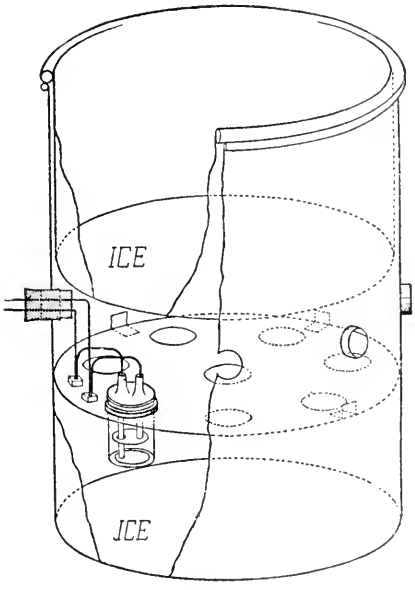

FIG. 3.

When the water was distilled from barium hydroxide, it was distilled first from a Jena glass balloon-flask and the vapor conducted into a retort also containing a little of the hydroxide. The water-vapor after leaving the retort was condensed in a tube of block-tin. By this means 10 to 15 liters of water could be obtained daily, having a conductivity of from 0.8 to 1.0×10^{-6} at zero.

BATHS.

The baths used for obtaining the various temperatures were constructed as follows. The zero bath is shown in fig. 3. The bottom of the bath into which the cells were plunged was filled with finely powdered ice moistened with a little pure water. The air above the cells was kept at very nearly zero by suspending just above the cells a pan filled with finely crushed ice moistened with pure water. In this way the solutions whose conductivities were to be measured at zero were kept to within 0.01 to 0.02 of zero.

*Amer. Chem. Journ., **19**, 91 (1897).

The second temperature at which the conductivity measurements were made was at first taken as that of the hydrant water. A reasonably constant temperature could be obtained by allowing a rapid stream of hydrant water to flow through a large vessel of water. This was soon abandoned and a temperature of 10°, 12.5° or 15° was obtained as follows: A stream of hydrant water was allowed to flow through a large tub of water, which was warmed by a small flame placed beneath, and the temperature was regulated by the thermoregulator described by Reid.*

The higher temperatures, 25°, 35°, 50° and 65° were obtained as follows: The water-bath used had the form shown in fig. 4. It consisted of a double-walled

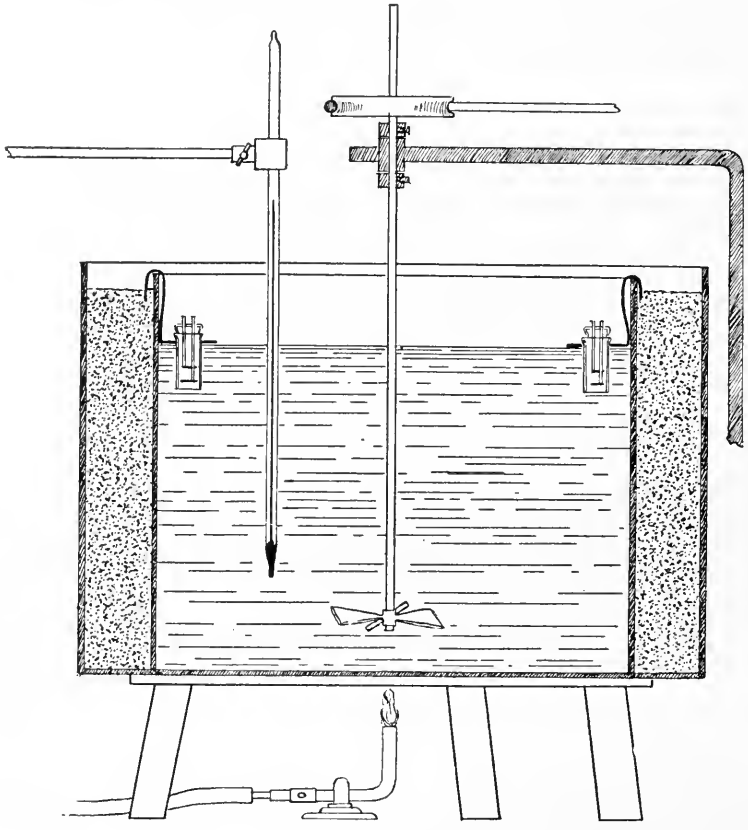

Fig. 4.

metal tub, the outer walls being 18 inches apart and the inner tub being 14 inches in diameter. The space between the two walls was filled with asbestos cement, which is a very poor conductor of heat. The inner vessel was filled with water, heated by a flame placed beneath and regulated by a thermoregulator. The top of the bath was covered with a neatly fitting piece of asbestos board. It was possible to keep any one of these baths to within 0.02° to 0.03° of the temperature desired. When working over the higher range in temperature the cells were kept over night in the 50° bath.

*Amer. Chem. Journ., **41**, 148 (1909).

INVESTIGATORS WHO HAVE WORKED ON THE PROBLEM.

The work recorded in this monograph has been done by twelve investigators, who have worked from one to nearly three years each upon the problem. Drs. Clover, Hosford, Howard, Kreider, Smith, and Winston worked one year each. Drs. Jacobson, Shaeffer, and Wight worked two years each, while Drs. Springer, West, and Wightman worked between two and three years each.

The following abbreviations are used after the name of the compound to show by whom the work in question was done; the first abbreviation referring to the investigator who worked over the range in temperature 0° to 35°, and the second abbreviation referring to the one who worked over the temperature range 35° to 65°. In a number of cases the same experimenter studied a given salt over both ranges in temperature. In these cases there is, of course, only one abbreviation.

C = Clover	J = Jacobson	Sm = Smith	Wt = Wight
H = Hosford	K = Kreider	Sp = Springer	Wm = Wightman
Hw = Howard	Sh = Shaeffer	W = West	Ws = Winston

THE RESULTS.

The volume of the solution, or the number of liters, that contain a gram-molecular weight of the electrolyte, is expressed by v. The molecular conductivity calculated by the equation $\mu_v = \frac{cva}{wb}$ is expressed by μ_v at the temperature in question; c being the constant of the cell, V the volume of the solution, a the reading on the arm of the bridge next to the rheostat, w the resistance in the box, and b the other arm of the bridge.

The percentage dissociation, represented by α, is calculated from the equation $\alpha = \frac{\mu_v}{\mu_\infty}$, μ_v being the molecular conductivity at the volume v, and μ_∞ the molecular conductivity at complete dissociation.

The temperature coefficients are expressed both in "conductivity units" and in "per cent." The coefficients in "conductivity units" are calculated thus—

$$\text{Coefficient} = \frac{\mu_v t_1 - \mu_v t}{t_1 - t}$$

where t_1 is the higher temperature and t the lower temperature. The coefficient in "per cent" is calculated by dividing the coefficient in "conductivity units" by $\mu_v t$, i. e., by the molecular conductivity at the lower temperature.

The values of α for some of the salts are not given. This is the case with those salts for which the value of μ_∞ was not nearly reached at the highest dilution used in this work. Such salts are nearly always strongly hydrolyzed by water, and this is the chief reason why the maximum molecular conductivity was not obtained at the highest dilutions employed. In such cases it is not possible to calculate even the approximate dissociation.

DISCUSSION OF THE RESULTS.

THE CONDUCTIVITY MEASUREMENTS.

The conductivities of about 110 salts and mineral acids have been measured and the results are herein recorded. These have been studied from about the most concentrated solution that could be prepared, up to a volume of from 1000 to 4000. The temperature range is from 0° to 65°. Salts of nearly all of the more common metals have been included within this work.

It is almost self-evident that in an investigation of this scope certain peculiarities would be presented by some of the substances studied.

The salts of lithium crystallize with more water than the corresponding salts of the other alkali elements. This means that the lithium ion is more hydrated in aqueous solution than the potassium, sodium, or ammonium ion. The result is that the lithium ion moves more slowly than the other alkali ions, and, consequently, the conductivities of lithium salts are smaller than those of the corresponding salts of sodium and potassium. Before we had the solvate theory it was very difficult to account for the fact that the lithium ion, which has a much smaller mass and smaller atomic volume than either sodium or potassium, should have a smaller velocity. But we now have the explanation of this fact. The larger conductivity of lithium sulphate, especially at high dilutions, as compared with other salts of lithium, is due to this being a ternary electrolyte, while the other three salts are binary electrolytes.

The salts of sodium with the simpler acids call for no special comment. The conductivities are larger than those of the corresponding salts of lithium, since the sodium ion is less hydrated than lithium, and, consequently, moves faster through the solution. Sodium carbonate has very great conductivity, especially at high dilution and elevated temperatures. This is undoubtedly due to large hydrolysis under these conditions. The very large conductivity of disodium phosphate is also probably due to hydrolysis. Sodium ammonium acid phosphate (microcosmic salt) begins, in fairly concentrated solutions, to give off ammonia at 25°, and this is still more marked at 35°.

The unusually high conductivity of sodium ferrocyanide, especially at $N = 1024$ and 65°, is due in part to the large number of ions yielded by this substance, and in part to hydrolytic dissociation.

The salts of potassium have somewhat larger conductivity than those of sodium. The potassium ion has less hydrating power than sodium, as is shown by the fact that potassium salts show less tendency to crystallize with water than sodium. Notwithstanding the greater mass of potassium, the ion moves faster than sodium, since it drags less water with it through the solution. This would increase the conductivity of potassium salts over that of sodium. The large conductivities of potassium carbonate, dipotassium phosphate, and tripotassium phosphate are due to hydrolysis. The large values for potassium nickel sulphate, and for both the violet and green potassium chromium sulphates are due chiefly to the large number of ions into which these compounds dissociate. It was shown some time ago by Jones and

Mackay* "that compounds of this type first break down into the constituent sulphates, especially in dilute solution, and these then dissociate as if they alone were present in the solution."

Potassium permanganate underwent slight decomposition, especially at more elevated temperatures. The high conductivity of potassium ferrocyanide is explained by the large number of ions into which it breaks down.

Ammonium salts with the ordinary mineral acids crystallize with little or no water. This means that the ammonium ion is very slightly hydrated in aqueous solution. Ammonium salts, in general, conduct to just about the same extent as potassium salts. Tetraethylammonium iodide decomposes slowly around 50 degrees.

Turning to the bivalent metals, let us consider, first, salts of calcium, strontium, barium, and magnesium. Most of the salts of these metals with the ordinary mineral acids crystallize with six molecules of water; calcium nitrate, which crystallizes with four molecules of water; strontium nitrate, which crystallizes anhydrous; barium chloride and bromide, which crystallize with two molecules of water each, and barium nitrate, which crystallizes without water, are exceptions.

Earlier work in this laboratory on the approximate composition of the hydrates formed by various substances† has shown that salts of calcium, strontium, barium, and magnesium hydrate to approximately the same extent, and that all four of these elements have very great hydrating power. While the masses of the atoms of these four elements vary from magnesium = 24.36, calcium = 40.1, strontium = 87.6, to barium = 137.4, yet the amounts of water with which these substances in solution are combined are so large that the total masses of the four ions when hydrated as they are, especially in dilute solution, are not very different. Further, the atomic volumes of these four substances are not very different, magnesium being somewhat less than the other three. Ionic velocity is a function of the ionic volume and ionic mass of the hydrated ions. We should, therefore, expect the velocities of these four ions to be just about the same, and such is the fact. The velocities are: Mg = 58, Ca = 62, Sr = 63, and Ba = 64.

Conductivity is a function of the number and velocities of the ions taking part in the conduction of the current. Since salts of the above four elements are dissociated to just about the same extent, it follows that salts of calcium, strontium, barium, and magnesium should give conductivities of the same order of magnitude. An examination of the results will show this to be the case. The salts of these elements with the organic acids—formic and acetic—are probably somewhat hydrolyzed, especially the salts of acetic acid. The formate showed a short hydrolysis time factor, while the acetate precipitated a small amount of barium hydroxide on the platinum plates.

Zinc nitrate, like magnesium nitrate, crystallizes with six molecules of water and the two have very nearly the same conductivity. There was evidence that zinc nitrate underwent slight hydrolysis. Zinc sulphate and magnesium sulphate crystallize with the same amount of water—each with seven molecules—and they have very nearly the same conductivities. Zinc acetate was undoubtedly strongly hydrolyzed, especially at the high dilutions and high temperatures. There was an appreciable odor of acetic acid in these solutions.

*Amer. Chem. Journ., **19**, 83 (1897). †Carnegie Institution Publication No. 60.

The salts of cadmium present several points of interest. The chloride crystallizes with two molecules of water, while the bromide and iodide crystallize without water. Notwithstanding the small hydrating power of the cadmium ion, its salts conduct less than the corresponding compounds of calcium, strontium, barium, and magnesium. The explanation of this is well known. The halides of cadmium are much less dissociated than the halides of the metals related chemically to it, hence the smaller conductivity.

The conductivities of the salts of manganese, nickel, and cobalt call for no special comment. Manganese nitrate underwent some decomposition at 35°. Nickel acetate underwent hydrolysis, the solution having the odor of acetic acid. Salts of these three metals give conductivities that are of the same order of magnitude, and are, indeed, very nearly equal. This would be expected from the relative hydrating power of the manganese, cobalt, and nickel ions.

The above comments also apply to the salts of copper that were investigated. At 65° these salts, in general, underwent decomposition, and the work, therefore, could not be extended to this temperature. The salts of aluminium, iron, and chromium are all quaternary electrolytes, *i. e.*, the molecule breaks down into four ions. The conductivities of these substances are, therefore, large. Many of these salts undergo hydrolysis at the higher temperatures. This is so pronounced with the salts of iron that they could not be studied at all at the higher temperatures. The salts of aluminium, iron, and chromium crystallize with large amounts of water, *i. e.*, these ions have great hydrating power. The order of magnitude of this power can be seen from the earlier work in this laboratory.* That these substances have very large temperature coefficients of conductivity will be seen a little later.

The salts of uranyl undergo hydrolysis, especially at the more elevated temperatures. To this hydrolysis there is an appreciable time factor. This accounts for the difficulties encountered by different workers in obtaining concordant results.

The relations pointed out above will be seen from the table of molecular conductivities on pages 70 and 71. Here the results are given at two dilutions widely removed from one another, and at three temperatures as widely different as possible.

A DEHYDROLYTIC TIME FACTOR.

An observation of some importance was made by Mr. Shaeffer. He took four parts of a $n/32$ solution of chromium chloride. One of these was kept at room temperature. A second was heated for two hours to 50°, a third for the same time to 65°, while a fourth was heated for two hours to 90°. All four solutions were then brought to the same temperature and their conductivities determined. The conductivities of all four solutions were taken at 35°, at 50°, and at 65°, and the results are given in the following table:

CHROMIUM CHLORIDE.

v	T	Not heated	Heated to 50°	Heated to 65°	Heated to 90°

The vessels used for holding the solutions were of Jena glass, which had been treated for months to remove all soluble matter. The increase in conductivity in the heated solutions could, therefore, not have been due to matter dissolved from the glass vessels. It will be seen that the solutions which had been heated had higher conductivity than those which had not. This is especially true of the solution which had been heated to 90°. This was undoubtedly due to hydrolytic dissociation of the salt into acid and base, and these did not completely recombine on cooling the solution to the initial temperature.

The same process was repeated, using a solution of chromium chloride which was $n/512$, heating one part to 50°, another to 65°, still another to 90°, then cooling all down to room temperature, and measuring the conductivities at the following temperatures:

Chromium Chloride.

v	T	Not heated	Heated to 50°	Heated to 65°	Heated to 90°
512	35°	487.4	489.5	500.6	559.7
512	50°	652.2	656.7	667.7	724.6
512	65°	842.5	843.8	856.6	915.1

The results for the more dilute solutions are of the same general character as those for the more concentrated.

To throw some light on the length of time required for the acid and base to recombine, the following experiment was carried out: The $n/512$ solution of chromium chloride, which had been heated to 90°, was cooled to room temperature and allowed to stand for 20 days. It was then warmed to 35°, and its conductivity determined. The value found was 508, while the value found shortly after heating was 559.9. The unheated solution gave a conductivity of 487.4. It is thus obvious that in 20 days the hydrolysis had not all disappeared.

A similar experiment with $n/512$ chromium chloride, which had been heated to 90°, cooled to room temperature and allowed to stand 20 days, and then warmed to 65° and its conductivity determined, gave the value 885. The conductivity shortly after heating was 915.1. The conductivity of the unheated solution was 842.5. This shows that the dehydrolysis, in this case, was not complete even after the solution had stood for 20 days. We propose to study these changes quantitatively in the near future, and see how long it requires for the completion of the dehydrolysis, in the cases especially of those salts which are strongly hydrolyzed.

The bearing of these facts on the purification of salts by recrystallization from water is important. The usual method of purification, by preparing a saturated solution at a higher temperature and then lowering the temperature and allowing the salt to crystallize is open to objection, especially for those salts which are strongly hydrolyzed by water. It has been supposed that when the solution in question was cooled down, the free acid and free base recombined. This work shows that such is not the case. There remains in the solution, for a long time, some free acid; and when the salt crystallizes from such a solution it is likely to occlude some of the free acid.

The better method for purifying hydrolyzable salts by crystallization is to make the saturated solution at low temperatures, and then remove the water by an air-pump or over sulphuric acid. It is well known that hydrolysis increases very rapidly with rise in temperature.

DISSOCIATION OF THE VARIOUS SALTS.

The dissociation of the various salts can be best compared and studied by bringing together the results for the different salts under comparable conditions. For some of the salts it is impossible at present to give their true dissociations. This is due to the fact that they underwent more or less hydrolysis, and the true value of μ_∞ for the unhydrolyzed salt was not obtained. In some other cases the dissociation may not have been complete, even in the most dilute solution investigated. In such cases the true value of μ_∞ would not have been reached. However, most of the dissociations given are nearly correct.

An examination of the preceding tables shows the following relations. The halogen salts of lithium are all dissociated to just about the same extent, the sulphate in the more concentrated solutions very much less.

The salts of sodium with the common mineral acids are all dissociated to just about the same extent, and slightly greater than the corresponding salts of lithium. This applies also to the sulphate in the more concentrated solution. Potassium salts of the common mineral acids show just about the same dissociation. The potassium salts of these acids are, in general, slightly more dissociated than the corresponding sodium salts.

The salts of ammonium are even slightly more dissociated than those of potassium. This points strongly to the correctness of the theory that ammonium hydroxide is a strong and not a weak base. Salts of strong bases are more dissociated than those of weak bases. The fact that ammonium hydroxide has small conductivity and is yet a strong base has been satisfactorily explained by Hantzsch. When ammonia is dissolved in water only a little ammonium hydroxide is formed, and this is strongly dissociated. Most of the ammonia in the presence of water remains there as ammonia and does not form the hydroxide with water. This explains the small conductivity of an aqueous solution of ammonia.

That ammonium hydroxide is a strong base is in keeping with the fact that ammonium salts of strong acids are so little hydrolyzed. Only the salts of comparatively weak bases with strong acids are appreciably hydrolyzed.

Salts of calcium, strontium, barium, and magnesium are dissociated to approximately the same extent, but considerably less than the corresponding salts of the alkali metals under the same conditions of dilution and temperature. Salts of zinc are dissociated somewhat less than those of magnesium. This applies especially to the halogen salts, which were not studied in this work because of the ease with which they break down with water.

The halogen salts of cadmium are dissociated less than those of any other known metal except mercury. What this means we do not know. The comparatively small dissociation of the cadmium halides is seen from the above table. The halides of mercury are scarcely dissociated at all, the aqueous solutions of these salts being practically nonelectrolytes, not conducting the current to any appreciable extent. The salts of manganese, nickel, and cobalt have approximately the same dissociation. These substances are dissociated to just about the same extent as the corresponding salts of calcium, strontium, barium, and magnesium. The same applies to the salts of copper. Lead salts show considerably less dissociation.

The salts of aluminium and iron are quaternary electrolytes, each molecule dissociating into four ions. The percentage dissociation, which, on account of hydrolysis can be taken only as an approximation, is much less than that of the salts of calcium, strontium, barium, magnesium, manganese, nickel, and cobalt.

TEMPERATURE COEFFICIENTS OF CONDUCTIVITY AND THE SOLVATE THEORY OF SOLUTION.

The temperature coefficients of conductivity are expressed both in conductivity units and in per cent. Certain relations between the coefficients in conductivity units and the solvate theory of solution have already been pointed out for a few substances.* We can now see how general these relations are. We have seen that the chief factor conditioning the increase in conductivity with rise in temperature is the increase in the velocities with which the ions move. If we assume that the force which drives the ions is constant, the velocity would be conditional chiefly by the viscosity of the medium through which the ion moves, and by the mass and size of the ion. The force that drives the ion would be greater at the more elevated temperatures, and the viscosity of the medium through which the ion moves would be less. Both of these factors would increase the ionic velocities and, consequently, the conductivity with rise in temperature.

There is, however, another factor which must be taken into account. That many ions in aqueous solution are hydrated seems now to be generally accepted. We have shown that these hydrates are relatively unstable; the higher the temperature the less complex the hydrate existing in solution. One example will make this point clear. In a normal solution of aluminium chloride, every molecule of the salt, or the ions resulting from it, is combined with about 30 molecules of water at the freezing point of the solution. Practically all of the water can be removed from such a solution by boiling it, except six molecules to one of aluminium chloride, this being the number brought out of solution as water of crystallization. The smaller the number of molecules of water combined with the ion the less the mass of the ion, and the less its resistance when moving through the solvent. Consequently, the ion will move faster the higher the temperature.

When we refer to the mass of the ion decreasing with rise in temperature, we do not refer to the charged atom or group of atoms which we usually term the ion, but to this charged nucleus *plus* a larger or smaller number of molecules of water which are attached to it, and which it must drag along with it in its motion through the remainder of the solvent.

The above conclusion can be tested by the results of experiment. If this factor of diminishing complexity of the hydrate of the ion with rise in temperature plays any prominent rôle in determining the large temperature coefficient of conductivity, then we should expect to find those ions with the largest hydrating power, having the largest temperature coefficients of conductivity. This condition can be tested by the results, as can be seen from the tables on page 77.

The hydrating power of a salt (or the ions resulting from it) is roughly proportional to the number of molecules of water with which the salt crystallizes. This is the same as to say that the salt which has the greatest power to bring water with it out of solution as water of crystallization would be the salt which, in solution, would combine with the largest amount of water. Water of crystallization is, then, a good general criterion of the degree of hydration in aqueous solution.

The approximate hydration of a large number of substances has, however, been worked out in this laboratory, and published in monograph No. 60 of the Publications of the Carnegie Institution of Washington. It will be seen that the substances in Table I have little or no water of crystallization, and are therefore only slightly

hydrated in aqueous solution. Those in Table II crystallize with very different amounts of water, but all with fairly large amounts of water. These substances are, therefore, much hydrated in aqueous solution.

It should be noted that the sulphates, single and double phosphates, chromates, bichromates, ferro- and ferricyanides, etc., are omitted from both of the above tables. The relations here under discussion do not apply to these more complex substances.

Let us now compare the temperature coefficients of conductivity, expressed in conductivity units per degree rise in temperature, for some of those substances which have slight hydrating power, with the corresponding coefficients for some of those compounds which have a much greater power to combine with water.

The volumes range from 8 to 1024, and the temperature coefficients are calculated between 25° and 35°, and between 50° and 65°. It will be seen, in general, that the substances in Table I have much smaller coefficients of conductivity at all dilutions and all temperatures than those in Table II. This is true, even when we take into account the fact that the substances in Table I are binary electrolytes—each molecule breaking down into two ions; while those in Table II are nearly all ternary electrolytes, each molecule yielding three ions, while the two salts of aluminium are quaternary electrolytes, each molecule breaking down into four ions.

Another fact of equal importance is brought out by comparing the results in Table I with one another, and similarly those in Table II with one another. If the temperature coefficient of conductivity is a function of the decrease in the complexity of the hydrate formed by the ion, with rise in temperature, then we might expect that *those substances which have equal hydrating power would have approximately the same temperature coefficients of conductivity.*

An examination of the above tables will show this to be true. The substances in Table I all have slight hydrating power, as would be expected from the fact that they all crystallize with little or no water. It will be seen that their temperature coefficients of conductivity are all of the same order of magnitude.

The compounds in Table II have different hydrating power, but all have very great hydrating power. Most of them, however, have hydrating power of the same order of magnitude. Indeed, this would be expected, since most of these substances crystallize with six molecules of water. There are a few substances in this table which crystallize with less than six molecules of water. Thus, barium chloride crystallizes with only two molecules, yet it forms hydrates of comparable complexity* with those substances which crystallize with larger amounts of water. That its temperature coefficients of conductivity are of the same order of magnitude as the other substances in the table is, therefore, entirely in keeping with the above relation. The hydrates formed by barium nitrate have not yet been worked out, so that it is impossible to say whether or not it presents an exception to the above relation, it crystallizing without water.

Manganous chloride crystallizes with only four molecules of water, yet the work of Jones and Bassett† has shown that it forms hydrates about as complex as the

*Carnegie Institution of Washington Publication No. 60.

†Amer. Chem. Journ., 33, 562 (1905); Carnegie Institution of Washington Publication No. 60, pp. 75 and 76.

other salts in Table II. Its temperature coefficients of conductivity are of the same order of magnitude as the other compounds included in this table.

The halogen salts of copper present apparent exceptions to the above relation. The chloride crystallizes with only two molecules of water, and yet has temperature coefficients of conductivity that are nearly as large as the salts with six molecules of water of crystallization. It might be inferred from this that this salt has much less hydrating power than the other compounds in Table II. The work of Jones and Bassett,* however, shows that this is not the case. Copper chloride has almost as great hydrating power as the compounds in this table which crystallize with six molecules of water. When we take this fact into account its temperature coefficients of conductivity are not surprisingly large.

Aluminium chloride crystallizes with six molecules of water, and aluminium nitrate with eight. They are, however, quaternary electrolytes, and their temperature coefficients are therefore larger than those of the ternary electrolytes. The hydrating power of these salts has been worked out† and has been found to be of the same order of magnitude as that of the ternary electrolytes in this table.

A third point brought out by the above tables is the following. *The temperature coefficients of conductivity for any given substance are greater at the higher dilution than at the lower.* This is satisfactorily explained on the basis of the above suggestion. The complexity of the hydrates at the higher dilutions is greater than at the lower, as has been shown by Jones and his co-workers, on the composition of the hydrates formed by different substances at different dilutions.‡

The hydrates being more complex at the higher dilutions, the change in the composition of the hydrates with change in temperature would be greater at the higher dilutions; and, consequently, the temperature coefficients of conductivity would be greater the more dilute the solution.

To summarize the above three points:

(*a*) The temperature coefficients of conductivity of aqueous solutions of salts, expressed in conductivity units, are greater the greater the hydrating power of the salt.

(*b*) The temperature coefficients of conductivity of aqueous solutions of electrolytes are of the same order of magnitude for those substances having approximately the same hydrating power.

(*c*) The temperature coefficients of conductivity for any given salt increase with the dilution of the solution, and this increase is greatest for those substances with large hydrating power.

All three of these conclusions are necessary consequences of the assumption that the large change in conductivity with change in temperature is due, in part, to the decreasing complexity of the hydrates formed around the ions, with rise in temperature. As these conclusions are verified by the experimental results, and as there seems to be no other assumption which would lead to these conclusions, we must accept the assumption which led to them as containing a large element of truth.

‡Carnegie Institution of Washington Publication No. 60.

HYDRATION AND IONIC VOLUME.

While discussing the hydrating powers of different ions, the following relation should be pointed out. Jones and Pearce,* after calling attention to the fact that the hydrating power of any salt is primarily a function of the cation, point out this relation:

If the atomic volumes of the elements are plotted as ordinates against the atomic weights as abscissas, we have the well-known atomic-volume curve. The curve contains well-defined maxima and minima. The alkali metals fall at the maxima of the curve. The three elements with the largest atomic volumes are potassium, rubidium, and cæsium. Salts of these metals usually crystallize from aqueous solution without water of crystallization, and they, therefore, have very little hydrating power. Lithium and sodium, some of whose salts crystallize with two and three molecules of water, and which, therefore, show some hydrating power in solution, have much smaller atomic volumes. At the minimum of the third section of the atomic-volume curve we find the elements strontium, iron, cobalt, copper, and nickel. The salts of these metals crystallize with relatively large amounts of water, and they show great hydrating power in solution. Aluminium, which has less than half the atomic weight of iron, but slightly greater atomic volume, falls at the second minimum of the atomic-volume curve. Its salts crystallize with six and eight molecules of water and show great hydrating power in solution.

Comparing the metals of the calcium group, we find that barium, whose salts crystallize with two molecules of water, has the largest atomic volume. The salts of the other elements of this group crystallize each with six molecules of water, with the exception of calcium nitrate, which crystallizes with four molecules. The magnesium ion, which has the smallest atomic volume of any element of this group, has the greatest hydrating power. Strontium, which has a slightly larger atomic volume than calcium, has a somewhat smaller hydrating power than calcium.

A careful examination of all of the evidence available shows that the *hydrating power of the cation is an inverse function of its atomic volume.*

This explains why it is that ions with large mass often have larger migration velocities than ions with smaller mass, which is the reverse of what would be expected. Thus, potassium, rubidium, and cæsium have larger migration velocities than sodium and lithium, notwithstanding the greater mass and volume of the former. This was for a long time inexplicable. We now have the explanation. Lithium and sodium have smaller atomic volume than potassium, rubidium, and cæsium, and, consequently, greater hydrating power. The hydrated lithium and sodium ions move more slowly, due to the atmosphere of the solvent which they must drag with them through the solution.

A large number of similar relations have been pointed out by Jones and Pearce.†

The question arises, Why this relation between hydrating power and atomic volume? It probably has to do with the electrical density upon the ion. The smaller the ion the greater the electrical density, and, consequently, the greater the power of the ion to condense molecules of the solvent upon it and hold them there in a state of loose combination.

*Amer. Chem. Journ., **38**, 736 (1907). †Ibid, **38**, 737–740 (1907).

It should be noted, before leaving the discussion of the temperature coefficients expressed in "conductivity units," that these coefficients in general increase with rise in temperature. This increase is only slight in the cases of those substances which are only a little hydrated, as will be seen in Table I. Table II shows a large increase in the coefficients with rise in temperature, and it will be recalled that this table contains those substances that have large hydrating power. This shows that the hydrates became more and more unstable the higher the temperature, there being more decomposition of the hydrates between 50° and 65° than between, say, 20° and 35°. This is what would be expected from the results already obtained in this laboratory* in connection with the effect of temperature on hydrates in aqueous solution.

Certain of the temperature coefficients from 35° to 50° are not given. This is due to the fact that one set of solutions was used from 0° to 35°, and an entirely different set from 35° to 65°. The solutions of these substances are more or less hydrolyzed, and probably have an hydrolysis time factor. Since the two sets of solutions of the substances in question stood for different lengths of time before using, this factor would make its influence felt.

The agreements, in general, between the two sets of results for the two sets of solutions at 35° were very good. In those cases where the deviations were more than a fraction of 1 per cent, the work, as has already been stated, was repeated.

TEMPERATURE COEFFICIENTS OF CONDUCTIVITY IN PER CENT.

The temperature coefficients of conductivity are also expressed in "per cent." These are the temperature coefficients in conductivity units divided by the conductivity at the lower temperature. The relations between the coefficients expressed in per cent can best be seen from the table on pages 82 and 83, which contains practically all of the salts studied in this investigation. The coefficients are given for two dilutions $V=8$ and $V=1024$, and over two ranges in temperature 25° to 35° and 50° to 65°. This will enable us to see the effect of dilution and of temperature on these coefficients.

The most striking feature of the table is the following: Take any one column, which gives the results for the different substances at the same dilution and temperature. It will be seen that for nearly all of these different types of salts, and the number is large, the temperature coefficients of conductivity in per cent is approximately the same; and not very widely removed from two, for $V=8$; and the range of temperature from 25° to 35°. There are some exceptions to this conclusion.

There are two lithium salts, the nitrate and sulphate, which are, the one much less, and the other much greater than two. Then there are exceptions among the complex salts. Potassium sodium sulphate, potassium chromium sulphate, potassium aluminium sulphate, and potassium ferrocyanide have values considerably less than two. Ammonium acid sulphate is a marked exception, the significance of which we shall try to work out in the future. Similarly, the green variety of ammonium chromium sulphate has a coefficient of only 1.38.

*Carnegie Institution of Washington Publication No. 60, 156 (1907).

The salts of calcium, strontium, barium, and magnesium have, in general, coefficients which do not differ widely from 2; although strontium nitrate has a value of only 1.79. It might be mentioned that strontium nitrate crystallizes without water. Zinc acetate also has a small coefficient, 1.59. This may be due to hydrolysis. Cadmium iodide, which crystallizes without water, has the large coefficient 2.27. Manganous sulphate has the rather small value 1.79, and copper sulphate has the same value. Aluminium sulphate has the very low value 1.57, chromium sulphate 1.61, and uranyl sulphate only 1.29.

Notwithstanding these apparent exceptions, there is unmistakably this general relation, that the temperature coefficients for $V=8$ and over this temperature range, for a large number of very widely different compounds, are very nearly the same and not widely removed from 2.

If we examine the other columns of data corresponding to other dilutions and other temperatures, we find relations similar to the above. Thus, for $V=1024$, and the temperature range 25° to 35°, the average value of the coefficient is a round 2.1. The average value of the coefficients for $V=8$, between 50° and 65°, is from 1.4 to 1.5, while the average value for $V=1024$, between 50° and 65°, is slightly greater.

We thus see that change in volume, range of temperature being constant, has very little effect on the temperature coefficients of conductivity expressed in per cent.

The effect of rise in temperature is to decrease the magnitude of these coefficients.

PART II.—ORGANIC ACIDS.

The Experimental Work in Part II was Carried Out by
Doctors Clover, Jacobson, Kreider, Smith,
Springer, White, and Wightman.

ORGANIC ACIDS.

The acids used were all obtained from Kahlbaum. Each acid was purified by the method best adapted to that particular acid, and its purity tested.

The method of work was, in general, the same as that followed with the inorganic salts. The cell constants were determined as in the work with salts. The following table of data will show how well the constants as calculated from three different readings with three different resistances agreed with one another, the table being taken from the work of Wightman; W being the resistance in the rheostat, b the distance on the wire from the point of contact to one end of the wire, and K the cell constants.

The first eight cells were used with the various dilutions of the acid. Cell A is the cell with cylindrical electrodes with very small constant, and was employed to determine the conductivity of the water.

Cells V, IV, II, and I were used to determine the molecular conductivity of a 0.002 normal and a 0.0005 normal solution of potassium chloride at 25°, these solutions being used to standardize the cells with small constants. The data show how concordant were the results obtained.

DISSOCIATION OF ORGANIC ACIDS.

The dissociation of most of the organic acids cannot be determined directly by simply increasing the dilution of the solution until complete dissociation is reached. The dilution at which μ_∞ would be reached for these weakly dissociated compounds would be so great that the conductivity method could not be applied to them. It is well known that we have an indirect method of determining the dissociation of

solutions of such weakly dissociated substances. This method is based upon Kahlrausch's law of the independent migration velocities of the ions. If we knew the value of μ_∞ for the sodium salt of the acid it is only necessary to subtract from this the constant for sodium and add the constant for hydrogen to obtain the value of μ_∞ for the acid in question. Thus:

$$\mu_\infty \text{acid} = \mu_\infty \text{HCl} + \mu_\infty \text{Na. salt of acid} - \mu_\infty \text{NaCl.} \quad (1)$$

The μ_∞ for hydrochloric acid, as calculated from the equation, $\mu_\infty = 245.4 + 6.06t - 0.00776t^2$, for the increase in conductivity with temperature (t = temperature), is 331.1 at 14.82°, while the value obtained by direct measurement is 331.0. The value of μ for sodium chloride at 12.13° calculated from the equation

$$\mu_\infty = 63.04 + 204t - 0.00823t^2$$

is 88.99, while the value found is 88.98.

From equation (1) we see that it is also necessary to know the value of μ_∞ for the sodium salt of the acid in question. This has been determined directly for a number of the acids.

Values of μ_∞ for the Sodium Salts of the Organic Acids.—Ostwald obtained μ_∞ for the sodium salts of the organic acids, by calculating the difference between the conductivity of sodium chloride at a certain dilution, *e. g.*, $V = 32$, and at infinite dilution. This difference he assumed to be constant for all sodium salts, and, therefore, by adding it to the conductivity of the sodium salt of any acid at the dilution $V = 32$, μ_∞ for that acid could be obtained. Instead of using this method in this investigation, μ_∞ for the sodium salts was determined directly from conductivity measurements.

The sodium salts were prepared as follows: A dilute solution of the acid (usually about $n/128$) was titrated with a standard solution of sodium hydroxide, using a drop of phenolphthaline as indicator. Alizarine is also a good indicator, and was used in later work because it is less sensitive to carbonic acid.

In a few cases the purified sodium salts were weighed out and made up to the desired concentrations. The sodium hydroxide used for titrating the organic acids was prepared as follows:

One hundred grams of sodium hydroxide, purified from alcohol, was dissolved in 100 grams of conductivity water (obtained as above described) and the concentrated solution was allowed to stand in a closed vessel for about a week. By that time practically all the carbonate, etc., was precipitated, and there was left a perfectly clear solution of sodium hydroxide, portions of which were pipetted out and diluted to the proper strength with conductivity water. The dilute solution was then standardized by means of the standard sulphuric acid, and otherwise. When thus prepared the solution is very nearly free from carbonate, as is shown by the fact that it does not give a precipitate of barium carbonate with barium hydroxide, and that when titrated with indicators, both those that are sensitive and those that are not sensitive to carbonates, the results are practically the same.

The conductivities of the sodium salts of a large number of the acids used in this work are given in the table on pp. 89 and 90.

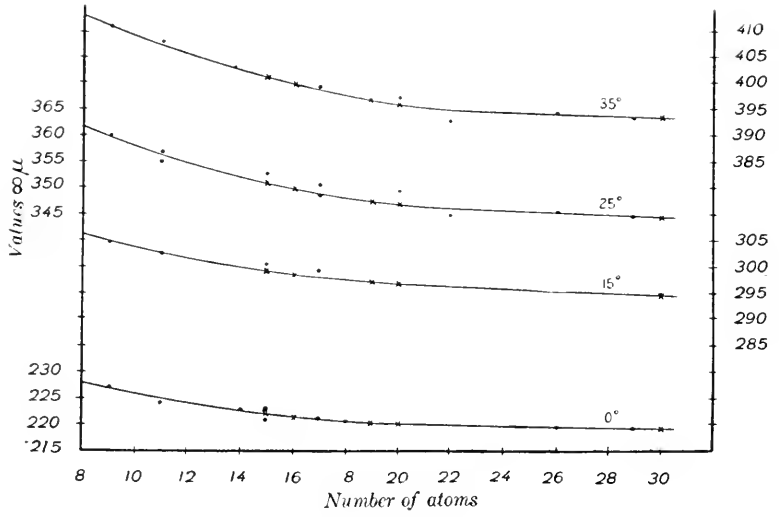

FIG. 5.

The μ_∞ for a number of the acids used in this work could not be determined as above described. These acids are di- or polybasic, and their sodium salts do not give a μ_∞ value even at a dilution of $n/4096$.

The method first used in this laboratory by Wightman for determining the μ_∞ for such acids is as follows: A curve was plotted in which the ordinates are the values of μ_∞ for a number of organic acids, and the abscissas are the number of

atoms in the molecules of the acids. These curves were drawn for the various temperatures used in the work.

By placing the dibasic acid in question in its proper position on one of these curves (the position being determined by the number of atoms in its molecule) the μ_∞ value for the acid can be read off at once.

To show how this method works the preceding figure (fig. 5) is given. The dots represent the positions of a number of acids on the curves, the asterisks the positions of a number of dibasic acids, whose μ_∞ values were found by this method.

DISCUSSION OF THE RESULTS WITH THE ORGANIC ACIDS.

It does not seem necessary or desirable, in discussing the results with the organic acids, to tabulate these results as was done in the case of the salts. The anions of these acids are not related as the cations of the salts were, and any relations must be of a more limited nature. Certain relations will, however, be pointed out, and they can easily be verified from the data for the various acids.

Take, first, the conductivities of the various acids: The presence of chlorine in acetic acid increases enormously its dissociation. Thus, at volume 32 and 0° the conductivity of acetic acid is 5.33; of dichloracetic acid 166, and of trichloracetic acid 208.7. The conductivity of cyanacetic acid under the same conditions is 68.7, and of phenylacetic acid 9. Acetic acid is slightly stronger than propionic, which at volume 32 and 0° has a conductivity of 4.63. This illustrates the general principle that in a homologous series of organic acids the lower members of the series are the stronger, at the same temperature and volume α-brompropionic acid having a conductivity of 38, β-iodopropionic acid of 12.57, while β-acetylpropionic acid has a conductivity of 5.85. Butyric acid at the same volume and temperature has the value 5.0; α-brombutyric 42.75, showing the marked increase in the strength due to the presence of bromine.

Isobutyric acid at volume 32 and 0° has the value 4.91, while hydroxyisobutyric has the conductivity 12.11, showing the increase in the strength due to the presence of the hydroxyl group. The conductivities of butyric and isobutyric acids are very nearly the same, which is characteristic of a large number of isomeric compounds. Isovaleric acid has the conductivity 5.36.

Turning to the dibasic acids of the oxalic series, we come first to oxalic acid. This was decomposed by the platinum plates, and was therefore not studied. Malonic acid

and a large number of its derivatives were investigated. The following table gives the results for two volumes and three temperatures for all of these substances:

Acid.	0°		25°		65°	
	$v=32$	$v=1024$	$v=32$	$v=1024$	$v=32$	$v=1024$
Malonic	43.51	153.3	72.23	251.2	.....	.....
Dimethylmalonic	32.00	124.1	51.23	198.93	77.1	299.26
Ethylmalonic	40.90	146.45	64.42	231.24	90.66	330.62
Diethylmalonic	92.77	201.22	138.84	311.98	186.22	462.78
Methylethylmalonic	45.89	156.21	72.45	248.19	104.35	365.54
Isopropylmalonic	40.07	144.1	64.92	234.00	91.73	343.8
Dipropylmalonic	103.16	203.51	154.54	317.78	.....	468.0
Butylmalonic	37.53	140.0	58.72	218.3	83.93	320.1
Benzylmalonic	45.06	153.05	69.82	239.44	97.76	345.35
Allylmalonic	45.62	158.93	71.47	248.67	101.16	358.28

The presence of two methyl groups weakens the acid, while two ethyl groups more than double the strength. Ethyl, methylethyl, isopropyl, butyl, benzyl, and allyl affect the conductivity very slightly. Dipropyl more than doubles the strength of the acid. These empirical relations have a certain kind of interest, but their meaning is at present not at all fully understood.

Succinic acid at zero and $v=32$ has a conductivity of 9.21, being much less than malonic. This is in accord with the relation pointed out between the strengths of acids and their position in an homologous series. Monobromsuccinic acid was studied at $v=128$. It had a conductivity of 101.46 against succinic at this volume of 18.24, showing that bromine increases acidity. Dibromsuccinic at volume 128 and 0° has the conductivity 254.34, showing the effect on acidity of the second bromine atom

Pyrotartaric at $v=32$ has $\mu_v=10.94$, μ_v for α-tartaric at $v=32=34.18$ and for racemic = 34.60. These two isomeric acids have practically the same conductivity.

The kind of isomerism, illustrated by maleic and fumaric acids stereoisomerism, is interesting in the present connection. We have seen that ordinary isomeric acids, using that term as we generally do, have very nearly the same conductivity. Maleic and fumaric acids at the same volumes and temperatures have widely different conductivities. Thus at $v=32$ and 0°, μ_v for maleic acid = 108.1, μ_v for fumaric = 35.46. The results for itaconic, citraconic, and mesaconic acids differ widely. For $v=32$:

μ_v for itaconic = 13.50 μ_v for citraconic = 68.66 μ_v for mesaconic = 33.31

Passing to the acids of the aromatic compounds, the introduction of chlorine into benzoic acid raises the conductivity at $v=64$ and 0° from 18.49 to 85.20. μ_v for orthonitrobenzoic at $v=128$ (0°) is 146.9, for metanitrobenzoic = 40.1. This shows the effect of chlorine and of the nitro group in the ortho position on the acidity. The 1, 2, 4 dinitrobenzoic at 0° and $v=32$, $\mu_v=166.51$, showing that the second nitro group in these positions still further increases the acidity. The 1, 3, 5 dinitrobenzoic at $v=512$ has a value for μ_v of only 122.28.

The effect of the nitro group in increasing acidity is well illustrated by picric acid. Phenol is a very weak acid, one of the weakest, while trinitrophenol is very strong. Its dissociation is of the same order of magnitude as the strongest mineral acids.

The effect of the introduction of the hydroxyl group into benzoic acid, on the

strength of that acid, depends upon the position of the group. Benzoic acid at zero and $v=128$ has a value of $\mu_v=18.49$. μ_v for salicylic or orthohydroxybenzoic acid $=62.65$, for metahydroxybenzoic $=20.48$, while for parahydroxybenzoic at 128 and $0°$, $\mu_v=18.29$.

The introduction of the second hydroxyl group raises the conductivity, the amount depending on the position of those groups. At zero and $v=128$, μ_v for 1, 2, 4 dihydroxybenzoic acid $=44.74$, while μ_v for 1, 2, 5 dihydroxybenzoic $=66.18$.

Gallic acid, or trihydroxybenzoic acid, has an interest of its own. For zero and $v=128$, $\mu_v=14.01$. The third hydroxyl, instead of raising, lowers the conductivity below that of benzoic acid itself.

The presence of the amino group lowers the strength of the acid, as would be expected. Thus, benzoic acid at $0°$ and $v=64$, $\mu_v=13.42$. For orthoaminobenzoic acid $\mu_v=3.07$; while for paraaminobenzoic acid $\mu_v=3.71$.

The four sulphonic acids studied are all strong, as are sulphonic acids in general.

Of the three toluic acids, the ortho is much stronger than the benzoic, while the other two are of the same order of strength. Cinnamic acid is slightly stronger than hydrocinnamic.

When we come to the dibasic phthalic acid, we have a much stronger compound than the monobasic acid. Thus, at $0°$ and $v=64$, μ_v for phthalic acid $=55.98$. The introduction of the second carboxyl thus increases the strength of the acid.

DISSOCIATIONS OF ORGANIC ACIDS.

It is not necessary to consider the dissociations of the several acids in detail. It is better to take up the constants calculated from the dissociations, since these are the quantities so often desired in connection with the organic acids. Some conclusions have, however, been reached, especially by White and Wightman, in connection with the dissociations of these compounds, and these will be given.

The conductivity of most of the organic acids is a parabolic function of the temperature, as is shown by comparing the values found with those calculated from interpolation formula. Several of the amino acids are exceptions to this relation, their conductivities not being a parabolic function of the temperature.

The effect of rise in temperature on the dissociation of organic acids can be formulated thus: The dissociation of some of the organic acids decreases regularly with rise in temperature from $0°$. Maxima occur in the dissociation of many of the organic acids. In some cases the maximum appears between $15°$ and $25°$; in others between $25°$ and $35°$, while in still other cases it falls at a higher temperature, *i. e.*, around $50°$. This is apparently not in accord with the Thomson-Nernst hypothesis, which connects the dissociating power of a solvent with its dielectric constant, and the dielectric constant decreases with rise in temperature.

The strong organic acids do not obey the Ostwald dilution law and, therefore, "dissociation constants" could not be calculated for them by means of this law.

Isomeric acids are not always dissociated to the same extent, and their dissociations change differently with rise in temperature.

The migration velocities of metameric ions are identical. The migration velocities of the anions of organic acids are a function of the number of atoms present in the anions. This fact is utilized to find the values of μ_∞ for the dibasic organic acids.

THE DISSOCIATION CONSTANTS.

The "constants" for the various acids are calculated by means of the Ostwald dilution law, $\frac{a^2}{(1-a)v}$ const. This, as is well known, does not apply to the strongly dissociated compounds, which therefore have no "constants." The constants are given for the volumes 32 and 1024, and for the temperatures 0°, 25°, and 65°.

Dissociation Constants.

These "affinity constants" are of fundamental importance in dealing with organic acids. From these values we learn more about the organic acids as acids than from any other data. The constants are tabulated for convenience of reference, and a glance will give a very good idea of the relative activities of a fairly large number of very different types of the acids of carbon.

TEMPERATURE COEFFICIENTS IN CONDUCTIVITY UNITS.

The following tabulation of some of the results will aid in an examination of these values. The heading 0° means zero to the next temperature.

The temperature coefficients of conductivity, expressed in conductivity units, increase rapidly with the dilution of the solution, and for weak organic acids, when not much hydrated, decrease rapidly with rise in temperature. When the acids are hydrated the temperature coefficients of conductivity are larger, and their increase with dilution and decrease with rise in temperature both take place at a slower rate.

The organic acids with the larger constants also have, in general, the larger temperature coefficients of conductivity expressed in conductivity units. The ortho acids usually have a somewhat larger coefficient than the meta and the para. The meta and the para have very nearly the same values for the temperature coefficients expressed in conductivity units.

TEMPERATURE COEFFICIENTS IN PER CENT.

The following coefficients in per cent were obtained; the heading 0° means from zero to next temperature.

The temperature coefficients of conductivity, expressed in conductivity units, are, for the same volume and temperature, of the same order of magnitude. Take $v=32$, and at 0° these coefficients range in general from 2.2 to 2.7. There are a few comparatively wide discrepancies. Thus α=brombutyric, dibromsuccinic, *o*-nitrobenzoic, and 1, 2, 4 dinitrobenzoic have percentage coefficients that are much lower than 2.2; while citric, coumaric, and especially metanilic and sulphanilic, have coefficients much larger than 2.7. That the relation pointed out above holds in general will be seen from the results. It will also be noted that the temperature coefficients in "per cent" decrease with rise in temperature.

The results recorded in this monograph are for 200 of the most frequently used salts and organic acids. Work along this same line is being continued in this laboratory. It is intended to include in this investigation a much larger number of salts, organic acids, the strong mineral acids and bases, and the organic bases in water and nonaqueous and mixed solvents.

INDEX.

THE ELECTRICAL CONDUCTIVITY, DISSOCIATION, AND TEMPERATURE COEFFICIENTS OF CONDUCTIVITY FROM ZERO TO SIXTY-FIVE DEGREES OF AQUEOUS SOLUTIONS OF A NUMBER OF SALTS AND ORGANIC ACIDS
